1 INTRODUCTION

Subdwarf B (sdB) stars are thought to have masses of about 0.5 $M_\odot$ with thin ($\lesssim 10^{-2} M_\odot$) hydrogen shells and temperatures from 22,000 to 40,000 K (Heber et al. 1984; Saffer et al. 1994). Shell hydrogen burning cannot be supported by such thin envelopes, and it is likely that they proceed directly to the white dwarf cooling track without reaching the asymptotic giant branch (Saffer et al. 1994).

Pulsating sdB stars with periods of a few minutes (officially V361 Hya, and also known as EC 14026 or sdBV stars) were first observed by Kilkenny et al. (1997), nearly simultaneous to their predicted existence by Charpinet et al. (1996, 1997). The sdBV stars have pulsation periods ranging from 90 to 600 s with amplitudes typically near or below 1 per cent. The pulsations are likely p modes driven by the $\kappa$ mechanism due to a diffusive iron-group opacity bump in the envelope (Charpinet et al. 1997; Jeffery & Saio 2007). Subdwarf B pulsators are typically found among the hotter sdB stars, with $T_{\text{eff}} \approx 34{,}000$ K and $\log g \approx 5.8$. Reviews of this pulsation class include an observational review by Reed et al. (2007a) for an of 23 resolved class members and by Charpinet, Fontaine & Brassard (2001) who described the pulsation mechanism. Another class of pulsating sdB stars have periods longer than 45 min, are likely g-mode pulsations and are designated V1093 Her, but commonly known as PG 1716 stars (Green et al. 2003; Reed et al. 2004a). General reviews of sdB stars and pulsators are of Heber (2009) and Østensen (2009). Our target is a p-mode, sdBV-type pulsator.

KPD 1930+2752 (also V2214 Cyg and hereafter KPD 1930) was discovered to be a variable by Billères et al. (2000, hereafter B00), who obtained data during four nights within one week. Their longest run was 5 h, yet within this limited data set, they detected 45 separate frequencies, which indicate that KPD 1930 is an interesting and complex pulsator. A velocity study confirmed the 217$^\text{m}$ binary period and, using the canonical sdB mass of 0.5 $M_\odot$, determined the companion mass to be $0.97 \pm 0.01 M_\odot$ (Maxted, Marsh & North 2000). As the companion is not observed either photometrically or spectroscopically, it is likely a white dwarf, placing the mass of the system over the Chandrasekhar limit. A study by Ergma, Fedorova & Yungelson (2001) suggested that the binary will shed sufficient mass to avoid a Type Ia supernova and will merge to form a massive white dwarf. With a rich, unresolved pulsation spectrum and the opportunity to learn some very interesting physics via asteroseismology, KPD 1930 was chosen for observation by the Whole Earth Telescope (WET). KPD 1930 also has an infrared companion $\approx 0.5$ arcsec away (Østensen, Heber & Maxted 2005).

2 OBSERVATIONS

KPD 1930 was the target of the WET run Xcov 23. Nearly 355 h of data were collected at 17 observatories from 2003 August 15 to September 9. The individual runs are provided in Table 1. Overall, these data have an observational duty cycle of 36 per cent which is less than typical WET campaigns. Because of the crowded field, most of the data were obtained with CCD photometers whereas some were obtained with photoelectric (photomultiplier tube) photometers. The photoelectric data were reduced in the usual manner as described by Kleinman, Nather & Phillips (1996). The standard procedures of CCD image reduction, including bias subtraction, dark correction and flat-field correction, were followed using IRAF packages. Differential intensities were determined via aperture photometry with the aperture optimized for each individual run with varying numbers of comparison stars depending on the field of view. Lightcurves are shown in Fig. 1.

We will also examine a small multisite campaign that obtained data during 2002 July. In total, almost 45 h of data were obtained from McDonald (the 21-m Otto Struve Telescope), San
Pedro-Martir (1.5 m) and Suhora (0.6 m) observatories. Specifics of these runs are given in Table 2.

As sdB stars are substantially hotter than typical field stars, differential light curves are not flat due to atmospheric reddening. A low-order polynomial was fitted to remove nightly trends from the data. Finally, the light curves were normalized by their average flux and centred around zero, so the reported differential intensities are \(\Delta I = (I/\langle I \rangle) - 1\). Amplitudes are given as milli-modulation.

amplitudes (mma), with 10 mma corresponding to 1.0 per cent or 9.2 mmag.

3 ANALYSIS

3.1 Orbital parameters

The largest variation in the light curve is caused by an ellipsoidal variation of the sdB star. In removing this variation to examine the pulsations, we can deduce some of the orbital properties. We defer attempting a complete binary solution to a work in progress (Pablo et al., private communication), but provide some basic information here that is obvious from the data. Non-linear least-squares (NLLS) fitting to the data (2002 and 2004) provides a frequency of ellipsoidal variation of $243.369 \pm 0.00007 \mu$Hz. The binary period is twice that at $8217.994 \pm 0.002$ s or $0.09511567 \pm 0.00000003$ d. Our value is within that found by B00 but outside the errors of the period determined by Geier et al. (2007, hereafter G07). G07 had 2900 spectroscopic data points unevenly scattered throughout 4 yr while we had 36 per cent coverage during 26 d in 2003 and $\sim$45 h spanning 7 d in 2002. As the epochs of our data overlap, period change can be ruled out and it is most likely that one (or both) of us is underestimating our errors. Fig. 2 shows modified X Cov 23 data folded over the binary period. The pulsations make the light curve very broad and it even appears that a pulsation frequency is an integer multiple of the orbital frequency (see Section 3.2). To transform the broad pulsation-included light curve into a narrower, pre-whitened form, we used our best data (Group II), pre-whitened by all 61 pulsation frequencies. Then we phase-folded the data over the orbital period, did a 60-point ($\approx 11.5$ s) smoothing and fitted an additional three frequencies. We then pre-whitened these three frequencies from the original, non-phase-folded data, phase folded again and smoothed by 60 ($\approx 11.5$ s), 168 ($\approx 30$ s) and 335 ($\approx 60$ s) points. The differently smoothed data did not affect the maxima and minima of the orbital variations, and so we used the 335-point smoothed data, shown as a solid line in Fig. 2, to examine the ellipsoidal variations.

Using radial velocity data, G07 estimate the orbital inclination as $i \sim 80^\circ$. At this inclination, the white dwarf companion should eclipse the sdB star. An eclipse is shown for $i = 80^\circ$ in fig. 8 of G07 and using the orbital parameters of G07, we produced a simulated light curve with BINARY MAKER 3 (Fig. 3). Our simulation was not intended to fit the actual data, but rather to illustrate the eclipse shape. From the simulation, the eclipse duration would be $\approx 164$ s or nearly three of our binned data points (at a binning of 335 points) with a depth of 0.2 per cent. While the observed minima are uneven, the shape and depth do not match those of an eclipse. We can therefore rule out inclinations for which an eclipse should occur, namely $i \geq 78.5^\circ$, based on G07. The uneven minima indicate what would

\footnote{See www.binarymaker.com.}
be expected based on the tidal distortion (gravity darkening). The gravity of the white dwarf makes the sdB star slightly egg-shaped. When the marginally sharper end faces us, the line-of-sight angle does not go as deep at one optical depth as it does when the blunter end faces us. This produces a fainter minimum when the sdB is farthest from us, and we view the slightly sharper end. A vastly exaggerated schematic of this is shown in Fig. 4 (a reconstructed image based on fig. 2 of Veen, van Genderen & van der Hucht)
2002). We fitted regions spanning 0.2 in phase with Gaussians to determine each maximum and minimum. The minimum at $\phi = 0.5$ is $0.18 \pm 0.03$ per cent fainter than the other minimum and using detailed models, this information, along with the amplitude of the ellipsoidal variation, should be sufficient to constrain the shape and limb darkening of KPD 1930. The uneven minima allow us to define the closest approach of the sdB star, and like Maxted et al. (2000), we define this as the zero-point of the orbital phase.

The light-curve maxima are also not quite even. Using the same Gaussian fitting technique, the maximum at $\phi_{\text{sdB}} = 0.75$, which is when the sdB component is travelling towards us, is $0.06 \pm 0.05$ per cent brighter than at 1.25, when the star is travelling away from us. Doppler boosting and Doppler shifting affect the flux by a factor of $(1 - v(t)/c)$ (Maxted et al. 2000; G07) which, using K1 from G07, should result in a Doppler brightening semi-amplitude of 0.11 per cent. This is at the 1σ upper limit of our measurement. Instead of using the measured velocity to deduce flux differences in maxima, two of us (SDK and HP) attempted to constrain the velocity from the light curve itself. Using low-pass filtering of the light curve, we obtained approximate values for the flux increase and converted those to velocity. The estimate of the maximum radial velocity is $529.76 \pm 16 \text{ km s}^{-1}$ which is of the same order as the radial velocity measurements of G07. The error estimate is the error of the fit to the light curve and does not include the (large) systematic error of the spectrum estimate. [More details about this measurement and its effects on the binary will be discussed in Pablo et al. (in preparation).] So Doppler effects could be responsible for the difference in maxima. Interestingly, such special-relativistic effects have been detected in another sdB binary at the expected level (Bloemen et al. 2011).

### 3.2 Pulsation analysis

In a standard manner for long-time-series data (i.e. Kilkenny et al. 1999; Reed et al. 2004b, 2007b), we analysed the data in several different groupings. We can use these groups to examine frequency and amplitude stability, look for consistent frequencies and amplitude variations. The groups are provided in Table 3, and pertinent sections of their temporal spectra [Fourier transforms (FTs)] are shown in Figs 5 and 6. Table 3 also lists the temporal resolution (defined as $1/t$, where $t$ is the run duration) and the 4σ detection limit determined for ranges of 1000–3000 and 8000–10000 μHz. Group I data include all of the XCov 23 data. Group II excludes noisy data, which is defined as a 4σ limit above 2 mma and has been trimmed so that for any overlapping data, only the best quality data were kept. Groups III, IV and V contain data obtained over 4 or 5 d of relatively good coverage during three different weeks of the 2003 campaign. Group VI is the 2002 small multisite campaign. Figure insets show the window functions, which are a single sine wave temporally sampled as the actual data. The central peak is the input frequency while other peaks are aliases which can complicate the data. Groups I and II are relatively well sampled, with alias peaks less than 40 per cent of the input amplitude whereas the remaining groups have obvious aliases that will contribute to the overall noise of the data.

A glance at the figures provides two simple observations as follows: (i) KPD 1930 is multiperiodic, pulsating in several tens of modes, confirming what was found in the discovery data (B00) and (ii) the pulsation frequencies are short-lived. This is evident from the fact that the highest amplitude peaks change between the shortest data sets (Groups III through VI) and the groups with the longest data sets (Groups I and II) have the lowest amplitudes.

As peak amplitudes in FTs show a mixture of the median amplitude and effects of phase stability, pre-whitening of the combined data sets could not be expected to accurately remove variations in amplitudes and/or phases (see Reed et al. 2007a; Koen 2009). However, because of the frequency density shorter duration data sets would likely have unresolved frequencies. This does not mean that least-squares fitting and pre-whitening are not of use; it is just that they need to be used with caution. We did the usual method of simultaneously fitting and pre-whitening the data using NLLS software independently for all the groups in Table 3 until we could not discern peaks (as in Fig. 7). However, because of the rich pulsation spectrum, we added an additional step. When searching the FT for pulsation peaks, we also plotted a window function made from the pre-whitening information gathered for all fitted frequencies. In this manner, we could view cumulative windowing effects and better judge the impact of pre-whitening on the FT. (A pre-whitening sequence of Group IV’s data is provided as Fig. S1 in the online Supporting Information.)

Frequencies were deemed intrinsic to the star if they were detected in at least two groups above the 4σ detection limits. Table 4 provides a list of detected pulsation frequencies. The first column lists a designation, the second gives the frequency from the highest temporal-resolution group and the NLLS error is given in parentheses. Subsequent columns list the fitted amplitude from each group (NLLS error in parentheses) along with any pertinent notes: NF indicates that the frequency was not NLLS fitted, and frequencies fitted, but off by a daily alias, are noted as $+\alpha$ or $-\alpha$ for 1 daily alias away or $++\alpha$ or $--\alpha$ for 2 daily aliases away. The last

Figure 4. Exaggerated simulated data showing how limb darkening, combined with ellipsoidal variation, causes uneven minima.
column notes other frequencies that are within 1 μHz of the daily alias as this could make pre-whitening difficult, depending on the window function. Table 5 lists other frequencies that we suspect are intrinsic to the star but did not meet our requirements. Fig. 7 is an expanded FT for Group II’s data. Each panel shows the original FT and the residuals after pre-whitening. The dashed (blue) line is the 4σ detection limit. There are regions where the residuals remain higher than the 4σ detection limit because either NLLS fitting and pre-whitening did not effectively remove all of the amplitude (most likely caused by amplitude and/or phase variations or another, unresolved frequency) or remaining peaks were not observable in the original FT.
3.3 The frequency content

In total, we detected 68 independent pulsation frequencies and 13 suspected ones. Here we summarize some generalities which will be used in subsequent sections. Only three frequencies are detected in all six data groups. Six other frequencies are detected in five data groups and 13 are detected in four data groups. 38 frequencies are within a 650-µHz region between 3650 and 4300 µHz. Unlike most sdBV stars, which contain several frequencies above 3 mmag, KPD 1930 does not have any in the integrated data (Groups I and II). Only $f_17$ has an amplitude of $>2$ mmag in all detections, though it is only detected in four groups. 11 of the 68

![Figure 6](http://mnras.oxfordjournals.org/) Same as Fig. 5 but for the frequency range from 4300 to 7000 µHz.
frequencies have Group I amplitudes of >1 mma and these always have higher amplitudes in the shorter data sets (Groups III through VI), if detected. These simple observations again lead to the conclusion that pulsations of KPD 1930 are highly variable in amplitude and/or phase over the course of our observations. Combining this with the density in the main region of pulsations will make accurate deciphering of the temporal spectrum difficult. Additionally, the pulsations in uncrowded regions have low amplitudes which will make them difficult to detect in short data sets.

4 DISCUSSION

4.1 Comparison with the discovery data

By combining their four nights of data, B00 obtained a resolution of 1.89 µHz and their estimate of a mean noise level is 0.021 per cent, giving their data a 4σ detection limit of 0.84 mma. By comparison, our XCov 23 data have 4.2 × better resolution and our detection limit is about half. Frequencies that match those of B00 are marked with a ⋄ in Tables 4 and 5 while those that are a daily alias away are marked with a ⋆. 26 of our 81 frequencies are related to the 44 frequencies listed in B00. Of the eight frequencies listed in B00 with amplitudes greater than 2 mma, seven are detected in our data. For comparison, there are 21 frequencies which we have detected in at least five of our groups or have amplitudes of >1 mma in at least two groups (one of which must be Group I or II), and of these, eight are related to frequencies detected in B00. This also indicates a substantial amount of amplitude and/or phase change since the B00 observations.

4.2 Amplitude and phase stability

KPD 1930 shows characteristics similar to the sdBV star PG0048+091 (Reed et al. 2007b), which has pulsation properties normally associated with stochastic oscillations. These properties include frequencies that are inconsistent between data sets and lower amplitudes in longer duration data. Of the 69 frequencies in Table 4, only \( f_{10}, f_{11} \) and \( f_{24} \) are detected in all six groups of data, while \( f_{2} \) is detected in five groups, with a peak just below 4σ in the sixth. Six more frequencies are detected and fitted in five of the six groups. Unfortunately, unlike PG0048+091’s well-spaced frequencies, most of those in KPD 1930 are packed tightly between 3600 and 4200 µHz. Outside of this main region of power, the amplitudes are quite low, making detection difficult.

Despite these complications, we analysed data sets of varying lengths with the goal of reaching time-scales shorter than the time-scale of amplitude and/or phase variations. Such data would be free of the resultant complications, allowing the amplitudes and phases to be more accurately measured. These could then be examined over the duration of our observations for changes. For the shortest possible time-scale, we examined every individual run for which the 4σ detection limit was better than 2.0 mma, totalling 32 runs. We also created 13 daily data sets combining low-noise runs that were contiguous or nearly so. The lengths of the daily data ranged from 7 to 27 h, with a median value of 16.5 h. Including the data for Groups III, IV and V, we have data sets sampling time-scales near 0.25, 0.67 and 4 d.

To resolve frequencies from individual runs and daily data sets, we selected frequencies isolated by at least 30 µHz from Table 4.
Table 4. Frequencies and amplitudes detected in various groupings of data. The temporal resolution of $1/(run length)$ and the $4\sigma$ detection limit are provided in the first two rows. Frequencies are in $\mu$Hz and amplitudes in mma with NLLS fitting errors given by the last digits in parentheses. The last column indicates other frequencies that are within 1 $\mu$Hz of the daily alias.

Note. + indicates that the frequency fit using NLLS was one daily alias (11.5 µHz) larger than that listed. Likewise, ++, – and −− indicate frequencies that are +2 daily, −1 daily and −2 daily aliases from those listed, respectively. ≈ indicates that frequencies were slightly more than 1σ away from that shown, <4σ indicates frequencies that had power in the FT which was below the 4σ detection limit; NF indicates frequencies above the 4σ limit that could not be fitted using our NLLS programme. △ indicates frequencies that match B00 while ⋆ indicates those that are a daily alias away.

Figure 8. Phases of frequencies resolvable from short data sets. Circles (black) indicate individual runs, triangles (blue) are from daily runs and squares (magenta) are for Groups III to V. Horizontal lines indicate the time-span of the data used in the phase determination for the daily and group sets.

4.3 Stochastic properties

An indicator for stochastic pulsations in solar-like oscillators is a $\sigma_A/A$ ratio near 0.52 (Christensen-Dalsgaard, Kjeldsen & Mattei 2001). Pereira & Lopes (2005) also derived this ratio and were the first to apply it in testing whether pulsating sdB stars could be stochastically excited. Their results for the pulsating sdB star PG 1605+072, based on seven nights of data, indicated that those pulsations were driven rather than stochastically excited. The ratios for $f_{60}$ and $f_{67}$ are near to this value. However in solar-like oscillators the amplitude decay time-scale is long compared to the re-excitation time-scale, and so this ratio may not be a good indicator for sdBV stars. Other features that could indicate stochastic oscillations include significant amplitude variability, amplitudes that are reduced in longer duration data sets (caused by phase variations) and match with simulated stochastic data.

Similar to what was done for PG 0048+091, we produced Monte Carlo simulations for stochastic oscillations with varying decay and re-excitation time-scales appropriate for the various data sets and groups we had for KPD 1930. As there are many amplitude ratios to work with from Table 6, it was hoped that tight constraints for amplitude variations could be deduced by matching the simulations with the observations. However, such was not the case and the...
best we could do was produce loose time-scales. The best results for $f_1$ indicate short amplitude decay time-scales (4–6 h) and long re-excitation time-scales (20–30 h), those for $f_2$ indicate medium decay time-scales (9–15 h) and medium to long re-excitation time-scales (12–27 h), those for $f_{44}$ indicate short decay time-scales (4–9 h) and medium re-excitation time-scales (8–16 h), those for $f_{60}$ indicate short to medium decay time-scales (4–15 h) and long re-excitation time-scales (25–40 h), and those for $f_{67}$ indicate short to medium decay time-scales (4–20 h) and long re-excitation time-scales (15–28 h). The resultant time-scales are fairly consistent in that the decays are always short compared to the re-excitations, but they are not nearly as clear as for PG 0048+091, certainly owing to the complexity of KPD 1930’s pulsation spectrum. However, the pulsation phases do not appear randomly distributed, as would be expected for stochastic oscillations. So we are left with some indications that stochastic processes may be present and some information contrary to stochastic oscillations. From these data, we cannot discern between them.

4.4 Observed multiplets

From the ellipsoidal variations in KPD 1930, we can strongly infer it to be tidally locked, which means that we also know the rotation period. In standard spherical harmonics, each $\ell$ can produce $2\ell + 1$ azimuthal values separated by the orbital frequency and the Ledoux constant (which is very small for p modes in sdB stars). We can search for multiplets to impose observational constraints on the mode degrees ($\ell$). Table 7 lists multiplets detected to splittings of four times the orbital frequency of 121.7 $\mu$Hz. As there are many pulsation frequencies related by a multiple of the rotation/orbital frequency, the order of the frequencies is the same as in Table 4 with the numbers in parentheses indicating the multiple of the rotation/orbital frequency between it and the previous (smaller) frequency. The leftmost frequency is just the lowest for each multiplet but has no significance otherwise.
Table 6. Properties of pulsation phases and amplitudes for frequencies separated by >30 μHz. Pulsation amplitudes are compared in a number of ways including by standard deviations (σ), average (⟨⟩) and maximum (Amax) amplitudes for various groupings of data. The number of possible detections is in parentheses next to the category (All, Individual, Daily or Groups).

4.4.1 Classical interpretation

In total, 61 of our 81 frequencies are related by a multiple of the rotation/orbital frequency. In a classical asteroseismological interpretation, we would assume that the spin axis is aligned with the orbital axis and the stars are tidally locked. As such, we are viewing the spin axis close to equator-on, or an inclination near 80° and the multiplets are caused by stellar rotation.

As each degree can have 2ℓ + 1 azimuthal orders, m, the number of orbital splittings provides a minimum ℓ value and constrains where the m = 0 is. For example, the f1, f2, f3 triplet is best interpreted as an ℓ = 1 triplet with m = 0 at f2. The multiplet beginning with f4 has sufficient frequencies to warrant an ℓ = 3 interpretation. However, ℓ = 3 modes have low amplitudes caused by geometric cancellation, making such an interpretation unlikely. More feasible is the fact that there are two ℓ = 1 multiplets with their outside components at a chance separation of nearly 2forb. Column 1 of Table 7 gives the minimum ℓ degree based on the number of orbital splittings. For entries with multiple possibilities, the most likely is given first. (The online Supporting Information includes a colour-coded figure showing the multiplets and a figure showing just the m = components with their corresponding degrees; Figs S2 and S3.)

We can also use the pulsation amplitudes to place some constraints on the modal degrees. Using Groups I and II as a guide, all of the amplitudes are within a factor of 7 of each other, while most are within a factor of 4. Table 8 lists the geometric cancellation factors for azimuthal orders ℓ, m = 1, 0 through 4, 4 for rotation axes of i = 70° and 80°. These factors indicate how much a pulsation amplitude would be reduced relative to a radial mode, which suffers no geometric cancellation. As Column 2 indicates, for the classical interpretation, all of the ℓ ≤ 2 modes have amplitudes reduced by factors less than 5–8, depending on orientation. This is roughly in agreement with the observed amplitude range. By contrast, all ℓ ≥ 3 modes have amplitudes reduced by factors of ≥20 (except for ℓ, m = 4, [1] depending on the viewing angle). Since we do not observe this range of amplitudes in KPD 1930, it is unlikely that these multiplets are being observed.

Ignoring high-degree modes, there remains multiplets as evidence of 12 ℓ = 1 and four ℓ = 2 modes. There are also 20 frequencies which show no relations to other frequencies via an orbital overtone. These are all candidates for radial modes. As there is no geometric cancellation for radial modes, they would be expected to have some of the higher amplitudes. f16, f18, f19 and f20 all have amplitudes greater than 1 mma for all of their detections. Yet none of these has amplitudes significantly higher than the other frequencies.
Therefore, it is also possible they are $\ell > 0$ modes with only one frequency visible.

4.4.2 Tipped-axis interpretation

Another interpretation would be that the pulsation axis is aligned with the tidal force of the companion. As described by Reed, Brondel & Kawaler (2005), such a pulsation geometry would process, completing a revolution every orbital period. The change in viewing geometry incorporates three additional pieces of information into the light curve which can be used to uniquely identify the pulsation degree $\ell$ and the absolute value of the azimuthal order $m$. These are a pattern of peaks in the FT of the integrated light curve, two or more $180^\circ$ flips in the pulsation phase over an orbital period and recovery of the ‘true’ peak in the FT of the phase-separated data. As in Reed et al. (2005), we will not seek analytic solutions, but will use simulated data of precessing pulsation geometries to guide us. These simulations and any tipped-axis analysis make the assumption that spherical harmonics apply.

We begin by searching for patterns in the FT of the integrated data of KPD 1930. To guide our search, we produced simulated data for modes from $\ell = 0$ to 4 for an orbital/rotation axis of $i_0 = 70^\circ$ and a pulsation axis of $i_p = 85^\circ$ relative to the rotation axis. This geometry seems reasonable for what we know of the orbital inclination and with tidal forces larger than the maximum Coriolis force. Changes of $5^\circ$–$10^\circ$ in either axis make little difference in the patterns. The simulated FTs are shown in Fig. 10. The amplitudes are relative to the $\ell = 0$ (radial) mode and along with the geometric cancellation factors of Table 8 indicate that high-degree modes are unlikely to be observed. The frequency patterns of Fig. 10 are what we are looking for in the observed data.

18 of the multiplets from Table 4 match patterns from simulated tipped-axis pulsations. The next step is to divide the data into orbital regions of like and opposing pulsation phases [Reed et al. (2005) showed this procedure in detail] for the different modes. If the intrinsic frequencies predicted by the tipped-axis model are recovered, and their phases are opposite in appropriate data sets, this would be a reasonable indicator of a tipped pulsation axis. As can be seen in Fig. 10, the intrinsic frequency for tipped modes $\ell, m = 1, 1; 2, 0; 2, 2; 3, 1$ and 3, 3 will have a corresponding frequency in the combined data. As such, recovering the peak in the divided data is less important but detecting a phase shift of 0.5 will be vitally important for associating these frequency patterns with tipped pulsation modes.

We separated the data for Groups I through V into orbital regions of like and opposing phases appropriate for modes $\ell, m = 1, 0$ through 4 and searched each group not only for the frequencies predicted from the observed multiplicities, but for any previously unobserved frequencies above the noise. The simplest data sets are those for $\ell = 1$ as the orbit is divided into halves, with set A of $\ell, m = 1, 1$ going from an orbital phase of 0.0 to 0.5 and set B covering the other half. Those for $\ell, m = 1, 0$ are shifted by $-0.25$ in phase. Table 9 provides the results of the search. Column 1 provides a unique mode identifier (with a corresponding identifier from Table 4 in parentheses, if there is any), Column 2 the frequency, Column 3 indicates the mode the data were phase-separated for and the remaining columns give the phase difference (set A – set B) for each group.

As anticipated considering the complexity of the data, the results are not straightforward. In the split data sets, the aliasing is significantly worse and the pulsation amplitudes are very low. Evidence also suggests that amplitudes and phases are changing throughout the campaign. Most of the predicted frequencies are not detected. Those that are detected have amplitudes only marginally above the noise. But the strongest evidence will be consistent phase differences of one-half in the various data sets. Frequency $r10 (f_{15})$ shows no phase shift between the sets for all groups and so cannot be a tipped pulsation mode. Frequencies $r11$ and $r14$ have intermediate values, again indicating that they are likely not tipped pulsation modes, but rather that their phases are not stable over the course of the observations. Frequencies $r12$ and $r13$ are only detected in two of the five data sets, and while one phase difference is near one-half, the other has an intermediate value. As $r2$ is also detected in the integrated light curve, but should not be for an $\ell, m = 1, 1$ mode, it is unlikely a tipped mode. Frequencies $r5$, $r8$ and $r9$ do fit what we expect for tipped pulsations. $r9$ is detected with a similar phase difference in all five groups, $r8$ has consistent phase differences for the three data sets in which it can be detected and $r5$ has consistent phase differences in three of four detections. Additionally, $r5$ is not detected in the integrated data, as should be the case. More surprising are the results for $r17$ and $r19$, both of which are only detected in two of the five groups but have phase differences near to one-half. These modes are unlikely to be observed because the geometric cancellation factors are very high (73 and 282, respectively), meaning the intrinsic amplitudes would need to be much higher than the others. Monte Carlo simulations were produced with random phases between data sets. This could be appropriate for purely stochastic pulsations, but for driven pulsations, the phases should not be random at all, but rather close to a fixed number. As tipped pulsations have a phase shift of 0.5 which is very unexpected for driven pulsations, the significance of the simulations is somewhat startling. Our phase detections for $r8$ and $r9$ only occur in 0.1 per cent of our simulations while those for $r5$ occur 1.0 per cent of the time. Those for $r17$ and $r19$ occur 6.7 and 4.9 per cent of the time, respectively.

2 These are shown schematically in Fig. S2 of the online Supporting Information.

3 The phased data sets for Group II with $\ell, m = 1, 0$ and 1, 1 are shown in Fig. S5 of the online Supporting Information.
Figure 10. Pulsation spectra of simulated data where the pulsation pole points 5° off the orbital axis, which has an inclination of 70°. The input frequency is at the centre (solid green line) and the dashed lines indicate orbital aliases. The amplitudes are relative to the radial mode and the mode is indicated on the right-hand side.

Of the 18 frequency multiplets in the combined data sets, three possess indicators for tipped pulsation modes. Nine have no detections at all, two have phase differences near zero and two more have marginally appropriate phase differences, but would indicate modes that are unlikely to be detected because of geometric cancellation. Still, particularly for $i_5$, which is not observed in the integrated data, the phase difference is a precise indicator for tipped pulsation modes. The chance of this occurring randomly is quite small.

4.5 Orbital dependence

While searching for tipped-axis pulsations, we stumbled upon the unexpected finding that some frequencies appeared to only occur for some stellar orientations.\(^4\) So we divided the data into four, eight and 10 subsets according to the orbital phase and examined the pulsation spectra of each. We found that quadrants, centred around the orbital phases 0 (QI), 0.25 (QII), 0.5 (QIII) and 0.75 (QIV) sufficiently differentiated the orbital dependence of the frequencies. Temporal spectra of Group II’s data, split into four quadrants, are shown in Fig. 11. The dashed lines indicate likely intrinsic frequencies while the dotted lines are more likely aliases, with the arrows indicating which frequency they are an alias of.

It is obvious that there is an orbital dependence on some frequencies, particularly $o_3$, which is clearly and only seen in QI. This most likely means that the pulsation geometry, as normally described by spherical harmonics, is more complex for these frequencies. Describing the pulsation geometry for such modes is beyond the scope of this paper, but we provide frequencies which have a detectable orbital dependence in Table 10. Outside of the main area of power, there is little sign of this uniqueness other than the fact that $f_{57}$ (5459) has a slightly higher amplitude in quadrant $\phi = 0.25$ and

\(^4\) These can be seen in Fig. S5 of the online Supporting Information.
plitudes to be fairly variable, although all investigation and we were unable to detect them in most of the sub-

5 RESULTS
We have analysed WET data spanning 26 d in 2003 August and
September, supplemented by 45 h of multisite data obtained in 2002
July. These data were used to examine the orbital properties and the
pulsation spectrum of the sdB + WD binary KPD 1930. We used the
ellipsoidal variation to affirm the orbital period and folded the data
over that period. No signs of eclipse were detected, constraining the
inclination to \(< 78.5\). Additionally, we noted that the minima are
uneven, indicating that KPD 1930 is very slightly asymmetric and
marginally detect anticipated Doppler effects from possibly uneven
maxima.
As implied from the discovery data (B00), we have found
KPD 1930 to be an extremely complex pulsator with frequencies
and amplitudes that can vary on a daily time-scale. In these data,
we confidently detect 68 pulsation frequencies and suggest a further
13. Of these, only 26 are related to frequencies observed by B00,
a surprisingly small number that attests to KPD 1930's pulsational
complexity. Our WET data, which covered more than three weeks
during 2003, have over four times better temporal resolution and
one-half the detection limit of B00.
We examined amplitude and phase stability by analysing subsets
of data over several time-scales for well-separated frequencies. Un-
fortunately, the low amplitude of these frequencies hampered our
investigation and we were unable to detect them in most of the sub-
sets. For the times we could detect them, we found the pulsation am-
plitudes to be fairly variable, although all \(\sigma_A/A\) ratios are short of
the value of 0.52 used in solar-like oscillators to indicate stochastic
oscillations (Christensen-Dalsgaard et al. 2001). The low ratio could
be an artefact of only a few amplitude detections or caused by an am-
plitude decay time-scale shorter than the re-excitation time-scale.
To investigate time-scales, we compared the observed amplitude
ratios for several subsets with simulated stochastic oscillations. The
simulations could easily fit the observed ratios and broadly found
decay time-scales near 12 h and re-excitation time-scales near 25 h.
As such, the pulsations do have some qualities normally associated
with stochastic oscillations; however, the phases are relatively sta-
ble which argue against stochastic oscillations. Hence, it is possible
that the amplitude variations have a different cause.
We have found 20 separate multiplets including up to 61 fre-
quencies. Assuming the classical interpretation which aligns the
pulsation axis with the rotation axis, these would indicate 12 \(\ell =
1\), four \(\ell = 2\) and/or possibly (but unlikely) four \(\ell = 3\), two \(\ell = 4\)
and one \(\ell = 5\) modes. We also searched for indicators of a tidally
induced tipped pulsation axis which would precess with each orbit.
While the complexities of the pulsations made searching for tipped
modes difficult, three frequencies were found which indicated that
tipped modes are present.
Two further modes have indications of tipped modes, but these
would indicate \(\ell = 3\) and 4, which are unlikely to be observed.
We also detected frequencies which only appeared during certain
orbital phases, which indicate that some frequencies are affected by
the slight asymmetry of the star. Fig. 12 schematically shows these
results with the height of the arrows indicating the degree (except as
noted below). Classically interpreted multiplet \(m = 0\) components
are shown as solid arrows (with multiple possible \(m = 0\) frequen-
cies connected by a horizontal line as in Fig. 10 and colour-coded in
the electronic version); modes from the tipped-axis interpretation
are shown as dashed arrows, with the \(m\) value above the arrow;
and frequencies which only appear during certain orbital phases
are shown as dotted arrows (at an arbitrary height of 1.5 since we
have no indication of their degree). Any frequencies that were not
involved in the above cases were (somewhat arbitrarily) deemed to
be \(\ell = 0\) modes and are indicated in the figure with solid arrows.
Note that the classically interpreted \(\ell = 1\) mode which could have
its \(m = 0\) component at 4453 or 4572 is marked with a question
mark. This is part of the tipped \(l, m = 3, 2\) multiplet and so if the
tipped mode is correct, then the classical mode would be invalid.
The small ‘3’ and ‘2’ under the axes are to indicate that there are
three and two closely spaced frequencies, all of which fit the condi-
tions we ascribe to \(\ell = 0\) modes that would be unresolvable in the
figure.

</tbody>
</table>
In the end, KPD 1930 is a star that incorporates a little bit of everything, many pulsation frequencies, multiplets, indications of a tidally induced pulsation geometry, non-sphericity, relativistic Doppler effects, amplitude variations and ellipsoidal variations, all wrapped up in a likely pre-Type Ia supernova binary. Unfortunately, all these effects complicate the analysis, making it a bit of an unruly mess. While we have tried to unravel it, our results indicate that even the WET fails to fully resolve the complexity of the pulsation spectrum and we can only imagine that perhaps Microvariability and Oscillations of Stars or Kepler-like data\(^5\) would be required to improve this situation. Unfortunately, the Kepler field just misses KPD 1930. KPD 1930 remains a fascinating star that warrants further attempts to understand its complexities.

Figure 12. Schematic of modes for KPD 1930. The modal degree ($\ell$) is indicated by the height of the arrow. Solid lines indicate the $m = 0$ component of classically interpreted multiplets. For those multiplets with more than one possible $m = 0$ frequency, they are connected by a dotted horizontal line. (They are also colour-coded in the electronic version.) The dashed lines indicate tipped-axis modes, with the $m$ index above the arrow, and the dotted lines indicate frequencies which show a dependence on the orbital phase (set to an arbitrary amplitude of 1.5, as no degree was ascertained for these frequencies).
